# Time Series Is Its Own Field of Statistics

- IF you want to study time series data, there is a separate series of courses you should take
  - Econometrics, dynamics, panel-data analysis, longitudinal regression analysis
  - Purpose of this lecture is to motivate main questions for those additional courses
- Notational changes
- Refer to “rows of data” by subscript  $t$  instead of subscript  $i$ 
  - some lingering effect of errors at  $t - 1$ ,  $t - 2$ , and so forth

# Autocorrelation in a Nutshell

- Suppose rows and columns are time points. OLS regression assumes

$$\text{Var}(e) = E(e \cdot e' | X) = \begin{bmatrix} \sigma_e^2 & 0 & 0 & 0 & 0 \\ 0 & \sigma_e^2 & 0 & 0 & 0 \\ 0 & 0 & \sigma_e^2 & 0 & 0 \\ \dots & & \dots & \dots & 0 \\ 0 & 0 & 0 & 0 & \sigma_e^2 \end{bmatrix} \quad (1)$$

- Note 2 critical simplifications are used
  - 1 All non-diagonal elements are 0
  - 2 All diagonal elements are equal to each other

## Autocorrelation in a Nutshell (2)

- Heteroskedasticity throws away simplification #2: allows differing  $\sigma_i^2$  values,

$$\text{Var}(e) = E[e \cdot e' | X] = \begin{bmatrix} \sigma_1^2 & 0 & 0 & 0 & 0 \\ 0 & \sigma_2^2 & 0 & 0 & 0 \\ 0 & 0 & \ddots & \dots & 0 \\ 0 & 0 & 0 & \sigma_{N-1}^2 & 0 \\ 0 & 0 & 0 & 0 & \sigma_N^2 \end{bmatrix}$$

but heteroskedasticity still leaves 0's on all off-diagonal elements

## Autocorrelation in a Nutshell (3)

- Autocorrelated errors: there are correlations “across time”

$$\text{Var}(e) = E[e \cdot e' | X] = \begin{bmatrix} \sigma_1^2 & \sigma_{12} & \sigma_{13} & \cdots & \sigma_{1N} \\ \sigma_{21} & \sigma_2^2 & \sigma_{23} & \cdots & \sigma_{2N} \\ \sigma_{31} & \sigma_{32} & \ddots & \cdots & \sigma_{3N} \\ \vdots & \ddots & \ddots & \sigma_{N-1}^2 & \vdots \\ \sigma_{N1} & \sigma_{N2} & \cdots & \cdots & \sigma_N^2 \end{bmatrix}$$

- $\sigma_{21} = \text{Cov}(e_1, e_2)$ , the covariance of the random error across observations on a unit
- $\text{Var}(e)$  is symmetric, because  $\sigma_{21} = \sigma_{12}$
- But otherwise, it can be arbitrarily complicated

# Consequences of Ignoring Autocorrelated Errors

- 1 OLS estimates of the  $b$ 's are unbiased and consistent
- 2 OLS gives the wrong (biased) estimates of the standard errors of the  $b$ 's. Thus the  $t$ -tests are bogus. The  $t$ -values are bigger than they should be, and you are likely to falsely reject the null hypothesis.
- 3 OLS is inefficient. There is an alternative estimation procedure (GLS) that gives estimates that are also unbiased and consistent, but also have lower variance.

# Spatial Autocorrelation

- Autocorrelation is not just for “time series” anymore.
- Work on spatial autocorrelation has intensified.
  - Refer to data points in a grid or a map
  - Hypothesize that disturbances at one cell may “disperse” themselves across other cells.

# Outline

## Consider one unit over time.

- One time series,  $x_t$  affects  $y_t$ , for  $t = 1, 2, 3, \dots T$
- The simplest model, the one with no complications, is fit with OLS

$$y_t = a + b \cdot x_t + e_t \quad (2)$$

- That's just one of the many possibilities, of course. Consider big horrible looking equation like

# Time Series as a Field of Study

$$y_t = \rho_1 y_{t-1} + \dots + \rho_p y_{t-p} + a + b_0 x_t + \dots + b_m x_{t-m} + \theta_0 e_t + \theta_1 e_{t-1} \dots +$$

- Lagged dependent variables,  $y_{t-1}, y_{t-2}, \dots$ : “autoregression models”
- Lagged exogenous variables,  $x_{t-1}, x_{t-2}, \dots$ : “distributed lag models”
- Lagged error terms,  $e_{t-1}, e_{t-2}, \dots$ : “autocorrelated error models” and “Autoregressive Conditional Heteroskedasticity”

# Cross Sectional Time Series

- Original Time Series studies focused on 1 data series, in isolation (psychologists would say “idiographic”)
- Collect several time series. What do you have? Names for same kind of problem:
  - Pooled Time Series
  - Cross Sectional Time Series
  - Panel Data Analysis
  - Repeated Measures
  - Longitudinal Analysis

# Outline

## Focus on $e_t$ : Autocorrelation = “serially correlated errors”

- Suppose we don't have lagged  $y$ 's or  $x$ 's on the right hand side.
- Do allow lagged errors.

$$y_t = b_0 + b_1x_t + e_t \quad (3)$$

- We consider only the distortion caused by lagged error terms, which are often called “disturbances”.
- This is not the same as saying the  $X$  is correlated with its own previous values, or that  $Y$  is. This only concerns the lingering effects of past “shocks”.

## Add an Equation for the Autoregressive Error

- AR(1), auto regression of order 1:

$$e_t = \rho e_{t-1} + u_t \quad (4)$$

- Error at time  $t$  includes

- a portion  $\rho$  of the previous (unmeasured) error, and
- a new random error, which “nice”

- 1  $E[u_t] = 0$  (unbiased)

- 2  $E[u_t^2] = \sigma_u^2$  (homoskedastic) and not autocorrelated  $E[u_t, u_s] = 0$

- AR(2) would introduce 2 lagged errors, as in

$$e_t = \rho_1 e_{t-1} + \rho_2 e_{t-2} + u_t \quad (5)$$

# The Durbin Watson Test for AR(1)

- This is only for AR(1).
- AND it is not correct when there are “lagged  $y$ ” values on the right hand side.
- General rule of thumb: DW should be “near 2” in order to reject the possibility that serial correlation exists, which means you affirm the claim  $\rho=0$ .

## DW Interpretation

- The theory is  $y_t = b_0 + b_1x_t + e_t$  and  $e_t = \rho e_{t-1} + u_t$
- If  $\rho = 0$ , then this is just the “regular old OLS model”. So the null hypothesis is  $\rho = 0$ .
- But the DW statistic equals 2 if the null is true.
- How close to 2 does it have to be? DW comes with 2 diagnostic limits,  $d_l$  and  $d_u$ .

DW far from 2 ( $< d_l$  or  $> 4d_o$ ) means that the null can be rejected.

DW very close to 2 ( $d_u < DW < 4 - d_u$ ), null accepted

If  $d_l < DW < d_u$  (or  $4 - d_u < DW < 4 - d_l$ ), then the test is inconclusive.

The indeterminacy is due to the possibility that autocorrelation in  $x_t$  may be causing the apparent autocorrelation in  $e_t$ .

# FGLS: Feasible GLS

## A Two Step Estimation Procedure

- 1 Theorize a correlation structure and “work out” an estimate of the error term’s variance/covariance matrix.
- 2 Use Generalized Least Squares to calculate estimates that best fit.
- 3 Repeat the procedure. The GLS fit  $\rightarrow$  estimates of the error covariances  $\rightarrow$  new GLS estimates.

## Generalized Least Squares

- Weighted Least Squares weights each error  $(y_t - \hat{y}_t)$  by  $w_t$

$$S(\hat{b}) = \sum_{t=1}^T W_t (y_t - \hat{y}_t)^2 = \sum_{t=1}^T (y_t - \hat{y}_t) w_t^2 (y_t - \hat{y}_t) \quad (6)$$

- Think of that like this: Multiply all “mix and match combinations”:

$$\begin{matrix} (y_1 - \hat{y}_1) \\ (y_2 - \hat{y}_2) \\ (y_3 - \hat{y}_3) \\ \vdots \\ (y_T - \hat{y}_T) \end{matrix} \begin{bmatrix} (y_1 - \hat{y}_1) \begin{bmatrix} w_1^2 & 0 & 0 & 0 & 0 \\ 0 & w_2^2 & 0 & 0 & 0 \\ 0 & 0 & \ddots & \dots & 0 \\ \vdots & 0 & 0 & w_{T-1}^2 & 0 \\ 0 & 0 & 0 & 0 & w_T^2 \end{bmatrix} \\ (y_2 - \hat{y}_2) \\ (y_3 - \hat{y}_3) \\ \vdots \\ (y_T - \hat{y}_T) \end{bmatrix} \quad (7)$$

- A sum with only  $T$  terms—the 0's in the weight matrix

## Generalized Least Squares (cont.)

- The Weight matrix for autocorrelated errors does not have all of those 0's
- So the carry out the “multiply and add” exercise:

$$\begin{array}{l}
 (y_1 - \hat{y}_1) \\
 (y_2 - \hat{y}_2) \\
 (y_3 - \hat{y}_3) \\
 \vdots \\
 (y_T - \hat{y}_T)
 \end{array}
 \begin{array}{c}
 (y_1 - \hat{y}_1)(y_2 - \hat{y}_2)(y_3 - \hat{y}_3) \dots (y_T - \hat{y}_T) \\
 \left[ \begin{array}{ccccc}
 w_1^2 & w_{12} & w_{13} & \dots & w_{1T} \\
 w_{21} & w_2^2 & w_{23} & \dots & w_{2T} \\
 w_{31} & w_{32} & \ddots & \dots & w_{3T} \\
 \vdots & \vdots & \ddots & w_{T-1}^2 & \vdots \\
 w_{T1} & w_{T2} & w_{T3} & \dots & w_T^2
 \end{array} \right]
 \end{array}
 \quad (8)$$

Leads to a sum with  $T \times T$  terms.

## Generalized Least Squares (cont.)

- Horrible, yes? The GLS Sum of Squares is a gigantic tangle if you write it all out

$$\text{row 1: } (y_1 - \hat{y}_1)w_1^2(y_1 - \hat{y}_1) + (y_1 - \hat{y}_1)w_{12}(y_2 - \hat{y}_2) + (y_1 - \hat{y}_1)w_{13}(y_3 - \hat{y}_3)$$

$$\text{row 2: } (y_2 - \hat{y}_2)w_{21}(y_1 - \hat{y}_1) + (y_2 - \hat{y}_2)w_2^2(y_2 - \hat{y}_2) + (y_2 - \hat{y}_2)w_{23}(y_3 - \hat{y}_3)$$

$$\text{row } T: (y_T - \hat{y}_T)w_{T1}(y_1 - \hat{y}_1) + (y_T - \hat{y}_T)w_{T2}(y_2 - \hat{y}_2) + \dots + (y_T - \hat{y}_T)w_T^2(y_T - \hat{y}_T)$$

$$= \sum_{t=1}^T \sum_{s=1}^T (y_t - \hat{y}_t)w_{ts}(y_s - \hat{y}_s) \quad (10)$$

- Use matrix algebra, this is a lot easier to write down.

$$(y - \hat{y})' W (y - \hat{y}) \quad (11)$$

## Generalized Least Squares (cont.)

- A big swirl of computations is involved in deriving the best fitting values of the coefficients.
- The solution looks like

$$\hat{b} = (X'WX)^{-1}X'Wy \quad (12)$$

## And Then Iterate (Maybe)

- An estimate of  $\hat{b}$  begets a new estimate of  $W$
- Then a new estimate of  $W$  begets a new estimate of  $\hat{b}$ .
- Repeat until estimates of  $\hat{b}$  converge.

# Cochrane-Orcutt for AR(1)

The most famous special purpose GLS estimator is the Cochrane-Orcutt procedure for AR(1).

**Step 1:** Get an estimate of  $\rho$ . To do so,

- a) estimate an OLS regression of  $y_i$  on  $x_i$
- b) call the residuals  $\hat{e}_t$
- c) estimate  $\rho$  in this model:

$$\hat{e}_t = \rho * \hat{e}_{t-1} + u_t$$

$u_t$  is a “nice” error term.

## Cochrane-Orcutt (Step 2)

Step 2: Use  $\hat{\rho}$  to create new weighted observed variables

$$y_t^* = y_t - \hat{\rho}y_{t-1} \quad \text{and} \quad x_t^* = x_t - \hat{\rho}x_{t-1} \quad (13)$$

Regress:  $y_t^*$  on  $x_t^*$ . That provides an estimate of  $\hat{b}_1$ .

And it provides a new set of residuals, so we can repeat step 1, then step 2, and so forth.

## Why Calculate $y_t^* = y_t - \rho y_{t-1}$ and $x_t^* = x_t - \hat{\rho} x_{t-1}$ ?

That's why Cochrane and Orcutt became famous.

- Restate the assumptions we have already made:

$$y_t = b_0 + b_1 x_t + e_t$$

$$y_{t-1} = b_0 + b_1 x_{t-1} + e_{t-1}$$

- Multiply through by the unknown constant  $\rho$ :

$$\rho y_{t-1} = \rho b_0 + \rho b_1 x_{t-1} + \rho e_{t-1} \quad (14)$$

- Subtract the third from the first:

$$y_t - \rho y_{t-1} = b_0 - \rho b_0 + b_1(x_t - \rho x_{t-1}) + e_t - \rho e_{t-1} \quad (15)$$

## Why $y_t^*$ and $x_t^*$ ?

Restate:

$$y_t - \rho y_{t-1} = b_0 - \rho b_0 + b_1(x_t - \rho x_{t-1}) + e_{t-1} - \rho e_{t-1}$$

Holy cow! Look at the error term. It is equal to our nice friend  $u_t$ .

$$u_t = e_t - \rho e_{t-1}$$

Step 2 is implemented, then, by calculating new variables  $y^*$  and  $x^*$  from the obvious equivalents in (15):

$$y_t^* = b_0(1 - \rho) + b_1 x_t^* + \dots + u_t$$

# Outline

## Focus on $x_t$ : Distributed Lag Models

- Sometimes people get excited because they think that “lagged” values of  $x_t$  matter.

$$y_t = a + b_0x_t + b_1x_{t-1} + u_t \quad (16)$$

- Its possible somebody wants to add a whole slew of lagged  $x$ 's.

$$y_t = a + \sum_{j=0}^m b_jx_{t-j} + u_t \quad (17)$$

These are often difficult to estimate (primarily because of multicollinearity).

- Clever choice of theory can simplify and make estimation possible (Almon lags, for example).

# ARIMA modeling.

- AR-I-MA: “auto regressive - integrated - moving average” modeling.
- A time series  $y_t$  is a combination of inputs from its own past and various input variables.
- The original intention of ARIMA modeling was to isolate trends and predict  $y_t$  without using independent variables as input.

## ARMA means No i “Integration Component”.

- ARMA model, with  $p$  lagged  $y$ 's and  $q$  lagged errors ( $e_t$ ):

$$y_t = \rho_1 y_{t-1} + \dots + \rho_p y_{t-p} + e_t + \tau_1 e_{t-1} + \dots + \tau_q e_{t-q} \quad (18)$$

- How many non-zero  $\rho_j$  coefficients are needed? How many  $\tau_j$  are needed? That's the magical, mysterious field of ARIMA modeling for you. Judgment, graphs, tests.
- *Note that “autoregressive” in this context has a different meaning!*
  - The AR part concerns the lagged  $y$ 's.
  - The MA part is the lagged unobserved error.

## More ARIMA notation

- Lag operator notation,

$$y_{t-1} = L(y_t) \quad (19)$$

$$y_{t-2} = L^2(y_t)$$

$$y_{t-3} = L^3(y_t) \quad (20)$$

- If you use that notation, then the big model above can be written:

$$y_t - \rho_1 L(y_t) + \dots + \rho_p L^p(y_t) = e_t + \tau_1 L(e_t) + \dots + \tau_q L^q(e_t) \quad (21)$$

- Which is the same as:

$$y_t(1 - \rho_1 L + \rho_p L^p) = \epsilon_t(1 + \tau_1 L + \dots + \tau_q L^q) \quad (22)$$

- Observed input variables  $x_t$  can be introduced. This is called an ARIMAX model:

$$y_t = \rho_1 y_{t-1} + \dots + \rho_p y_{t-p} + \beta_0 x_t + \tau_0 \epsilon_t + \tau_1 \epsilon_t + \dots + \tau_q \epsilon_{t-q} \quad (23)$$
